**MECHANISM OF FORMATION AND AGE OF THE AYYARMALAI A-TYPE  
CHARNOCKITE – GRANITE ASSOCIATION FROM THE SOUTH-EASTERN  
PALGHAT-CAUVERY SHEAR SYSTEM, SOUTHERN INDIA**

**ABSTRACT**

The Ayyarmalai A-type charnockite and A-type alkali granite lies on the south-eastern margin of the Palghat-Cauvery Shear System and provides an example of co-magmatism that was later overprinted with granulite facies metamorphism at ~2.45-2.5Ga. The Palghat-Cauvery Shear System represents an intriguing zone with Neoproterozoic aged granulites (~800-500 Ma) to the south and Archaean granulites (~3000-2500 Ma) to the north; the origins of which are still often disputed. This study presents whole rock major and trace element compositions, mineral chemistry, pressure-temperature estimates and whole rock Sm-Nd, Rb-Sr, Pb-Pb and  $\delta^{18}\text{O}$  isotopic compositions of this A-type charnockite-granite association found at Ayyarmalai, Tamil Nadu, Southern India. The subsequent data from this study suggests that: (1) the Ayyarmalai charnockites from the Palghat-Cauvery Shear System have zircon ages that are synchronous with events in the Northern Granulite Terrain; (2) The Dharwar Craton is a strong candidate for the protolith of these rocks; (3) Evidence of a Neoproterozoic-Cambrian granulite metamorphic event (~520 Ma) appears to be absent in these rocks questioning the existence or location of a Neoproterozoic - Cambrian suture zone proposed for the Palghat-Cauvery Shear System recently.

U-Pb zircon ages show zoned igneous cores ~2.65-2.68 Ga ages in both rock types defining the crystallisation age, while the large metamorphic rim overgrowths date the Archaean granulite metamorphic event at ~2.45 - 2.5 Ga. Geochemical data of the Ayyarmalai charnockites reveal a very primitive, unfractionated REE pattern with no Eu-anomaly, ferroan, high K-calc-alkaline, with moderate enrichment of LREE with respect to HREE and fall within the field of high Ba-Sr type granitoids. Extraction of Pyroxene- Hornblende rich cumulates resulted in an intermediate charnockite driving the crystallisation towards the final A-type alkali granite. The A-type alkali granite show a more fractionated REE pattern with a significant Eu-anomaly, ferroan, high-K- calc-alkaline, with enrichment of LREE and depletion in the low Ba-Sr type granitoids.  $\epsilon\text{Nd}$  and Nd model ages indicate

a highly evolved protolith ( $\epsilon_{Nd}(0) = -25.15$  to  $-33.14$ ) that encountered a crustal Archaean source (2.89-3.09 Ga) causing contamination as the magmas ascended. Harker diagrams, Nd data (isochron age, ~2519 Ma) and U-Pb zircon crystallisation ages suggest a co-magmatic relationship between the charnockite and alkali granite. Conventional geothermometry/barometry suggest minimum pressure-temperature conditions existed at 740 – 750°C and P=5.61 – 5.84 kbar.

The data presented from this study is consistent with a magmatic origin of these charnockites favouring the early crystallisation of orthopyroxene. The correlation with the data from the Dharwar Craton suggest that the study region may have encountered Dharwar Craton on magmatic ascent causing crustal contamination.

## 1. INTRODUCTION

Over a century ago, a hypersthene bearing granite was identified in a tombstone belonging to a Job Charnock in Calcutta by T.H. Holland. He located the source of the rock to quarries at Pallavaram, a suburb of Madras (now called Chennai). In a paper read to the Asiatic Society of Bengal, he detailed its petrological features and subsequently named it after the deceased by calling it a charnockite (Holland, 1900). The Southern Indian Granulite Terrain (SIGT) is well endowed with kilometres of charnockitic rock exposures which occur mainly as highland massifs lying along a network of major shear zones (Fig. 1a). The SIGT is separated into blocks and cratons divided by these shear zones that show traces of a dynamic tectonic history from Early Archaean to Cambrian (Chetty *et al*, 2006; Ghosh *et al.*, 2004). Charnockite formation makes up a significant part of the magmatic and metamorphic history of India and thus it is only fitting that these rocks have become subject to such extensive research over the last century.

### 1.1 Charnockite Definition and Problem

The IUGS define a charnockite as an “*Opx bearing granite composed mainly of quartz, perthite or antiperthite and Orthopyroxene (usually hypersthene), as an end member of the charnockite series*” (Le Maitre, 2002; Streckeisen, 1974, 1976). The charnockite series accounts for variants that have been recognised across different charnockites usually based on the differing modal abundance of the dominant feldspar i.e. opx- bearing granodiorites (charno-enderbite), opx-bearing tonalites (opdalite), opx- bearing monzonites (mangerites) and so forth (Le Maitre, 2002; Rajesh, 2004). Charnockites also vary from being acidic (and rich in quartz and feldspar) through to basic (and rich in olivine and pyroxene), which correspond mineralogically with many other igneous terms (Washington, 1916) i.e. diorites, norites and so on. Therefore charnockite is merely a general term (*senso lato*) that can be used until further geochemical analysis can discriminate the rocks into more specific categories.

The obvious ambiguity in this general term has led to a series of problems; one being the inconsistency and incorrect usage of nomenclature around when the term charnockite is applied. In

one case the term charnockite (an igneous term) has been applied to orthopyroxene (opx) bearing granites a part of an established igneous suite and on the other hand it has been applied to orthopyroxene bearing para and orthogneisses derived from granulite facies metamorphism. This has arisen through differing processes (igneous and metamorphic) that generate almost identical mineral assemblages (the key mineral in this case being hypersthene). Charnockites can be generated through several different mechanisms:

(1) Metasomatic dehydration granulite facies metamorphism involving the volatile fluxing of a low H<sub>2</sub>O (high P<sub>CO<sub>2</sub></sub>) and/or alkali-halogen fluid. The influxing of a low H<sub>2</sub>O fluid initiates the breakdown of hydrous minerals i.e. biotite and hornblende resulting in orthopyroxene (Smith *et al.*, 1979; Newton, 1989).

(2) Intrusion of water-undersaturated magma in dry crust during, or with subsequent, granulite facies metamorphism (Martignole, 1979).

(3) *In Situ* dry anatexis during granulite facies metamorphism (Martignole, 1979).

(4) Fractionation from enriched mantle-derived mafic magmas and/or crustal assimilation by mantle magmas. Differentiation of the parent magma can result in a cumulate or residue (after the granitic melt is removed) that is of charnockitic composition (Kilpatrick and Ellis, 1992; Field *et al.*, 1980; Frost and Frost, 2008; Pride & Muecke, 1980; Nesbitt, 1980). These charnockites also commonly display A-type granite characteristics.

There are several examples of igneous and metamorphic charnockites included in the literature, however given that charnockites are commonly found in granulite- facies metamorphic terrains, evidence of the original precursor are then reset or obliterated making it extremely difficult to distinguish which process crystallised the orthopyroxene resulting in a charnockite.

## **1.2. Characteristics of Igneous and Metamorphic Charnockites**

In the SIGT, charnockites occur mainly as highland massifs and are usually interpreted as being the igneous type charnockites, as well as this; waxy green veinlets, selvages and patches occurring in the surrounding rocks that contain a charnockite composition were interpreted as incipient charnockites. Incipient charnockite is a term used to represent early stages of charnockite formation driven by the

influx of CO<sub>2</sub> rich fluids (Peucot *et al.*, 1989; Naha, 1988). There have been several research papers over the last decade that attributes the Southern Indian charnockites to be a product of the CO<sub>2</sub> metasomatic dehydration granulite facies metamorphism mechanism (Janardhan *et al.*, 1982; Bhattacharya & Sen, 2000; Santosh *et al.*, 1991; Frost & Frost, 1987; Bradshaw, 1989; Perchuk *et al.*, 2000; Hansen *et al.*, 1987, Raith & Srikantappa, 1993; Dobmeier & Raith, 2000; Tsunogae *et al.*, 2002; Santosh, 1985).

From many other localities around the globe there are clearly igneous charnockites that exist mainly as a part of a magmatic suite. This is where the magmas have differentiated into a series of rock types and in the case of charnockites there are several examples in the literature where charnockites occur a part of an Anorthosite-Mangerite-Charnockite-Granite Suite (AMCG Suite) around the globe e.g. The Adirondacks in New York (McLelland, 2002; Emslie, 1992); Korosten, Ukraine (Shumlyansky *et al.*, 2006) South-eastern Brazil (Janasi, 2002); Rogaland Complex in Southern Norway (Duchesne & Wilmart, 1997). Characterising these charnockites is difficult as the geochemistry, isotopic and mineral compositions are widely variable suggesting, a variety of tectonic settings. However, attempts to categorize igneous charnockites have suggested they are rich in TiO<sub>2</sub>, K<sub>2</sub>O and P<sub>2</sub>O<sub>5</sub>, have distinct iron-enrichment trends but due to the variable amongst individual charnockite plutons this is subject to debate (Kilpatrick & Ellis, 1992). Many attempts to split charnockite types into groups based on mineralogies have defined some interesting trends i.e. garnet-bearing vs. garnet-absent, low SiO<sub>2</sub> vs. high SiO<sub>2</sub> and garnet-rich vs. hornblende-rich. Rajesh (2008) shows that high SiO<sub>2</sub> charnockites display geochemical characteristics of alkali A-type granitoids, while low SiO<sub>2</sub> display similar trends with fractionated calc-alkaline granitoids similar to Caledonian type granitoids (Pitcher, 1982).

Santosh *et al.* (2005), has attributed charnockite formation in the SIGT to a CO<sub>2</sub> flushing origin, where CO<sub>2</sub> is derived from decarbonation of carbonate lithologies or from deep seated mantle sources leading to the generation of charnockite usually during granulite facies metamorphism (Santosh & Omori, 2005; Tsunogae *et al.*, 2008). Another model involves underplating of the crust by mantle-derived magmas (Tomson *et al.*, 2006; Newton, 1992; Rajesh, 2008). This study will compare these mechanisms with that of a subduction environment (where charnockite may be generated as syn-

accretion magmas), a compressional setting, an intraplate rift, or a plume-type setting, in hope to better constrain the tectonic environment in which these charnockite – granite associations were formed.

This paper will assemble valuable geochemical, petrological, isotopic (radiogenic and stable) and geochronological data on an A-type, high K calc-alkaline charnockite and alkali granite pair from Ayyarmalai; the south eastern end of the Palghat-Cauvery Shear System. The combined data aims to discriminate whether the charnockite from this area was crystallised from the mantle or was originally an igneous rock that was metamorphosed at granulite facies grade to a charnockite. This will hopefully provide some insight into links between charnockite – granite associates and where these rocks fit into the geological history of India and to a wider extent, eastern Gondwana.

## **2. GEOLOGICAL SETTING**

### **2.1. Geology of India**

#### *2.1.2. Dharwar Craton and the Northern Granulite Terrain*

During the Archaean, various cycles of geodynamic evolution took place in several cratons whereby an episode of island arc accretion was followed by the development and formation of tonalite - trondjemite - granodiorite (TTG) greenstone terranes. This led to a period of reworking of the crust accompanied by tectonics, the emplacement of calc-alkaline granites and the development of high grade metamorphism. This is widely represented in the Dharwar Craton (central southern India) and contains some of the oldest rocks in the world (Chadwick, 1997; Jayananda *et al.*, 2000; Jayananda *et al.*, 2006; Rogers, 1986) (Fig. 2a). In the northern part of the Dharwar Craton includes low to high grade volcanic-sedimentary rocks surrounded by more extensive areas of TTG Peninsular gneisses (Peucat *et al.*, 1989; Miller *et al.*, 1996; Mohan and Jayananda, 1999; Ghosh *et al.*, 2004). These TTG-greenstone terranes are intruded by a later synkinematic calc-alkaline to K-rich magmatic bodies along with a N-S sinistral shear zone dividing the Western and Eastern Dharwar Cratons (WDC and EDC respectively) (Chadwick *et al.*, 2000). In the WDC, Mesoarchaeon TTG Peninsular gneisses are overlain by Late Archaean greenschist belts intruded by numerous granitic plutons (~2.6-2.68Ga) (Chadwick *et al.*, 2000; Jayamanda *et al.*, 2000). While in the EDC, the dominant lithologies consist

of Neoproterozoic N-S trending granodiorite to granitic gneisses. The Proterozoic greenstone belts containing continental and oceanic-like volcano-sedimentary rocks that are interspersed within the granitic gneisses have experienced greenschist to amphibolite facies metamorphism (Miller *et al.*, 1996; Braun and Kriegsman, 2003; Ghosh *et al.*, 2004). Data suggests that protolith ages in the Dharwar craton range from 2.9-3.6 Ga (Beckinsale *et al.*, 1980; Harris, 1994; Bartlett *et al.*, 1998) and it is suspected that the southern part of the Dharwar craton experienced a late Proterozoic (~ 2.5 Ga) high temperature-low pressure metamorphic event (~8 kbar, 800°C) synchronous with the emplacement of granites (Buhl *et al.*, 1983; Hansen *et al.*, 1984). This area of Proterozoic granulites is referred to in this study as the Northern Granulite Terrain (NGT), an area just north of the Palghat-Cauvery Shear System (Fig 2b). It is dominated by large highland charnockitic massifs and lowland granitic ortho- and paragneisses varying from amphibolite to granulite grade of metamorphism (Ghosh *et al.*, 2004; Clark *et al.*, 2009; Mojeizes *et al.*, 2003). Various data has suggested that these northern granulites are metamorphosed rocks from the Dharwar Craton (Ghosh *et al.*, 2004; Tomson *et al.*, 2006; Plavsa *et al.*, unpublished).

### 2.1.3. Southern Granulite Terrain

The Southern Indian Granulite Terrain (SIGT) is a significant terrain of high grade (amphibolite - granulite facies) rocks involving multiply deformed Proterozoic and Neoproterozoic magmatic and high grade metamorphic rocks (Santosh & Tsunogae 2003; Cenko & Kriegsman 2005; Chetty *et al.* 2006). Isotopic data, geological mapping and U-Pb geochronology of rocks from the SIGT in the past decade has indicated a diachronous evolution with regional thermotectonic and high-grade metamorphic events occurring at ~2.5 Ga and ~550 Ma. In the Southern Granulite Terrain, the older granulites are overprinted by a Neoproterozoic-Cambrian high T granulite event at around 0.55 Ga (Bartlett *et al.* 1995; Collins *et al.*, 2007; Clark *et al.*, 2009; Santosh *et al.*, 2003). The peak granulite facies metamorphism conditions calculated from various areas in the SGT constrain *P-T* conditions ranging from 700-1000°C and 5-12 kbar (Harris *et al.*, 1992; Raith *et al.*, 1997; Santosh *et al.*, 2003; Satish-Kumar *et al.*, 2002). Nd model ages range from 2.0 to 3.0 Ga (Bhaskar Rao *et al.*, 2003; Choudhary *et al.*, 1992; Harris *et al.*, 1994; Jayananda *et al.*, 1995; Brandon & Meen, 1995; Bartlett *et al.*, 1998;

Meissner *et al.*, 2002) except in the Achankovil Nd Unit where younger model ages are recorded (1.3–1.6 Ga; Harris *et al.*, 1994; Brandon and Meen, 1995; Bartlett *et al.*, 1998). This last metamorphism has been attributed to final accretion of Gondwana during the East African and Malagasy orogeny discussed later (Santosh *et al.*, 2003, 2009, Collins *et al.* 2007a, Collins *et al.* 2007b, Collins & Pisarevsky 2005).

## 2.2. Palghat-Cauvery Shear System

The Archaean and Neoproterozoic blocks of the SGT are separated by a prominent east-west tectonic zone (~70 x 400km), which in this study is referred to as the Palghat-Cauvery Shear System (PCSS) as it contains numerous narrow anastomosing network of dextral shear zones. This zone essentially separates the Neoproterozoic Southern Granulite Terrain from the Archaean/Palaeoproterozoic Northern Granulite Terrain and the Dharwar Craton. The zone also splits the SIGT into blocks called the Madras, North, Nilgiri and Madurai blocks. The Madurai block is separated by the Achankovil Zone further south from the Trivandrum block (Figure 2a). The PCSS, being at the interface of two different aged crustal blocks therefore represents an important zone for research. A number of tectonic models have been proposed for the PCSS, including:

- (1) The PCSS forms the focus of either an ancient suture zone i.e. the continuation of the ancient Betsimisaraka suture of Gondwana that is evident in Madagascar and continues along this shear zone (Collins & Pisarevsky 2005; Collins *et al.* 2007; Cenko & Kriegsman 2005; Chetty *et al.* 2006, Santosh *et al.* 2009).
- (2) It is a zone of transpressional tectonics in a convergent regime or merely a region of intense reworking of Archaean crust during the Proterozoic (Harris *et al.*, 1994; Bhaskar Rao *et al.*, 2003; Santosh *et al.*, 2003).
- (3) A dextral transcurrent shear belt (Drury *et al.*, 1984).
- (4) A collapsed marginal basin (Drury and Holt, 1980).

Geochronological signatures show three major ages at ca. 2.5 Ga, 1.8 Ga and 0.55 Ga which advocate a magmatic event, detrital zircon ages from metasediments and a granulite facies metamorphic event respectively. Rocks from the PCSS have given Nd model ages of 3.0-2.2 Ga suggesting that the shear

zone rocks are mainly reworked material from the high grade crustal domains to the north and south (e.g. Meißner *et al.* 2002).

This study is located at Ayyarmalai, a site existing south east of the PCSS, a much understudied part of the system where the majority of the data has been obtained from the central and western sides. Limited knowledge on relationships between the SIGT and the adjacent Dharwar craton is also poorly understood therefore further data collection from this boundary would prove vital to delineating the tectonic history of Southern India.

### **3. FIELD RELATIONSHIPS & SAMPLE PETROGRAPHY**

The samples collected for this study all lie within the PCSS near a small village called Ayyarmalai (10°52'48.48"N, 78°23'17.52"E); which is approximately 34km South East of Karur Township, 9km South of the Cauvery River, in Tamil Nadu, Southern India. Sample locations were recorded using Global positioning system (GPS) readings to record precise locations; Table 1 outlines sample locations, including GPS reading, rock type and the map units and Figure 2c shows a map of these localities. Samples were chosen to best represent the study area incorporating all of the mineralogical variability. Therefore the main rock types in the Ayyarmalai area have been categorised into: hornblende and garnet rich charnockite varieties, mafic charnockite zones, charnockitic gneiss zones, pink alkali granite, grey granite containing waxy green coloured dehydration zones and a later stage of cross-cutting hornblende-bearing pegmatites and quartzofeldspathic veins (Table 1).

#### **3.1. Field Relationships**

The field site for this study borders the town of Ayyarmalai (*Malai* meaning Hill), where a prominent 311m pink granite hill outcrops. The pink granite has a coarse, massive texture without any visible foliation but what appears to have flow induced folding. Pink feldspar is the dominant constituent with subordinate plagioclase and quartz and accessory biotite. The medium- to coarse-grained pink granite is veined locally by 0.5 to 1.0 m thick pegmatites and minor quartz. To the west

of the town there are excavated quarries where the rock types that have been exposed consist of extensive massif charnockites. The charnockite massif is faintly but recognizably foliated (the average trending Dip/Dip Direction, 38/250) and contains numerous quartz veins, large mafic blebs and pegmatites, all very dark in colour making it hard to distinguish between them in the field. Between the charnockite and the western front of the pink granite is a thick unit of grey granite contain green-grey waxy lenses and patches interpreted as dehydration zones.

### **3.2. Ayyarmalai Quarry Massif Charnockite**

Charnockites have been subdivided into four types; the first two consist of hornblende rich charnockites existing to the western sides of the quarries and to then to the eastern sides of the quarries the assemblages are dominated more by garnet rather than hornblende. A third form of charnockite occurs as large mafic blebs consisting of dominantly hornblende, pyroxenes and Fe-Ti Oxides which appear to float in the homogenous massif charnockite and in this study these have been referred to as mafic charnockite zones. Visible on some walls of the quarries there are charnockites that have undergone high strain and formed a gneissosity with small sigma porphyroblasts that all have south side up movement indicators. These are referred to in the study as charnockitic gneiss zones.

#### *3.2.1. Garnet & Hornblende Rich Charnockites*

The charnockites are medium to dark greenish-grey rocks, within an even, medium-grained granoblastic texture, varying to porphyroblastic. K-feldspar (perthitic to mesoperthitic and microcline), plagioclase and quartz are the main matrix minerals while hornblende, pyroxene and Fe-Ti oxides (ilmenite and magnetite) dominate the mafic minerals. Accessory minerals consist of apatite, iron oxides, magnetite, zircon and rarely allanite.

The mineral assemblage of these charnockites consists of:

**(1)** *Quartz + plagioclase + K-feldspar + orthopyroxene + clinopyroxene + hornblende + garnet ± Ilmenite ± biotite ± apatite ± magnetite ± zircon.*

The matrix assemblage in these samples consists of plagioclase, K-feldspar and quartz which have tight convolute interlocking (Figure 3q). Hornblende, ilmenite, magnetite and pyroxenes loosely define a foliation in some samples. Variable modal proportions of clinopyroxene and orthopyroxene in these rocks reach up to 20%. Where orthopyroxene occurs lying in close association is usually plagioclase, clinopyroxene, ilmenite and hornblende. In several instances, ilmenite is rimmed by clinopyroxene and hornblende and in some instances clinopyroxene occurs as cores within orthopyroxene. In these cases, clinopyroxene has a very high birefringence and displays lamellae textures. Hornblende displays a greenish-brown colour in plane light and displays well developed crystal cleavages. Hornblende is commonly intertwined with magnetite and biotite laths in these rocks. Plagioclase displays polysynthetic twinning while quartz shows some undulose extinction and there is minor myrmekite adjacent to biotite laths. Zircon abundance in charnockites appears quite high as numerous zircons over the assemblages apparent in thin section slides and even shows distinct zoning at this level. Small apatite crystals surrounded by radial cracks are also evident.

The assemblage of garnet rich charnockites from the Ayyarmalai quarries are the same as hornblende rich charnockite however the difference lays where garnet overtakes the dominance of hornblende. Garnet-rich charnockites have large garnet porphyroblasts dominating the assemblage and these occur closely with hornblende. Minor ilmenite, hornblende and quartz inclusions in garnet may represent an earlier stage (prograde) before the attainment of granulite facies conditions.

### *3.2.2. Mafic Charnockite zones*

Amongst the homogenous charnockite are patches are very dark, mafic bleb zones. These zones appear to concentrically change in composition from the outer rim to inwards. The outermost rim is very rich in quartz and hornblende and then progressively inwards the middle of these patches is dominated by hornblende (dark green in thin section), magnetite/ ilmenite, pyroxene, quartz with minor plagioclase and garnet. These zones appear to float amongst the homogenous waxy green coloured hornblende and garnet rich charnockite varieties.

### 3.2.3. Charnockitic Gneiss Zones

The gneissosity in charnockitic rocks is defined by alternating bands and streaks of mafic and felsic minerals (Figure 3d). In these rocks the felsic bands are dominated by K-feldspar, Plagioclase and quartz, while the mafic bands which also defined to foliation through the alignment of these minerals consist of hornblende and biotite. In the mafic bands there are subordinate pyroxenes and reaction textures between biotite and myrmekite. Mineralogically, these charnockites differ in the modal abundance of quartz (5-20%) as opposed to the other charnockite samples that have a more granitic composition with a higher modal abundance of quartz (~20%).

## 3.3. Ayyarmalai Alkali Granites

### 3.3.1 Pink Alkali Granite

The dominant Ayyarmalai pink granites are medium grained, equigranular to granoblastic textures with a simple granitic composition. These are abundant in quartz (45%), K-feldspar (40%) with mafic minerals (10%) and accessory minerals (5%).

The mineral assemblage of these pink granitic rocks consists of:

The Ayyarmalai pink granite has a granoblastic texture with convolute interlocking between grains. The matrix assemblage consists dominantly of K-feldspar (microcline and Perthite), plagioclase and quartz. Biotite in these assemblages contains ilmenite and quartz inclusions, are very rounded in shape. Other mineral features include plagioclase showing polysynthetic twinning and titanate which has radial cracks surrounding the mineral. In some samples hornblende and biotite define a lineation. Original igneous textures appear to have been obliterated by high grade metamorphism affecting the area. Zircons on top of the assemblages are clearly visible, however not as abundant as charnockite samples.

### 3.3.2. *Grey Granite*

Along the western front of Ayyarmalai consists of grey granite almost identical in modal compositions with the exception of the presence of bottle green clinopyroxene (Fig.3m-n). Clinopyroxene sometimes displays corroded cores and well developed crystal cleavages (Figure m-n). Microcline is the dominant K-feldspar mineral and again these have convolute interlocking textures in the matrix. The assemblages also contain titanite and ilmenite with radial cracking surrounding the grains. Other interesting features are the bright red colour of feldspars in hand sample specimens and the abundance of dehydration veins and selvages throughout the grey granite zone (Figure 3c).

### 3.3.3. *Dehydration Zones*

Waxy green-grey selvages run through the grey granite and bear striking resemblance to metamorphic charnockite (or “incipient charnockites”). The main assemblage of these dehydration zones consist of K-Feldspar + quartz + plagioclase  $\pm$  Ilmenite  $\pm$  magnetite. Microcline and microperthite dominate the felsic minerals. There is a high quantity of high birefringence fractures that intersect the minerals in these samples. The absence of orthopyroxene in these indicates that they are not charnockites, therefore these patches have been labelled as dehydration zones due to the absence of hydrous minerals.

### 3.3.4. *Pegmatite*

These a very coarse grained intrusions dominated by K-feldspar and quartz. Accessory minerals involve magnetite and hornblende. K-feldspar phenocrysts are large (<30cm in width) and the inner zones concentrate clusters of hornblende and magnetite (<3cm size grains). The pegmatites cross cut the pink granite and grey granite foliation (or flow induced folding), as well as the dehydration zones and quartz veins, representing the last stage of crystallisation.

## 4. ANALYTICAL PROCEDURES

### 4.1. Petrography

Identification of minerals and analysis of reaction textures of the various rock types were performed using field and lab petrography. First hand mineral identification was performed in the field by identification of hand specimens and field relationships. Standard thin sections of all the thirty two samples were made and used to identify minerals more closely examining mineral and reaction textures. This included 9 massif charnockites, 2 charnockitic gneisses, 5 mafic charnockite, 1 pegmatite from the quarry, 5 pink granites from Ayyarmalai, 3 grey granite, 2 dehydration veins occurring within the grey granite and 1 pegmatite samples from this area.

Quantitative analyses of the minerals were performed using polished thin sections of the main lithological types; garnet-rich charnockite, a hornblende-rich charnockite, the grey clinopyroxene-bearing granite and the pink alkali granite, were performed using Electron Microprobe CAMECA SX51 Electron Microprobe w SAMX Software housed at the University of Adelaide. The microprobe was calibrated to analyse minerals for the oxides Si, Mg, Fe, Ti, Al, Na, K, Ca, Mn, P, and also included F and Cl. This data was then recalculated using molecular weights of elements and minerals, the cation numbers as well as the oxygen numbers which then was used to calculate the cation quantities in the minerals. This determines the dominate end members involved in minerals occurring in these rocks.

#### *4.1.1 Pressure-Temperature Estimates*

Mineral chemistry data obtained from the Microprobe processes discussed above were used to input into a Plagioclase – Hornblende thermometry program to estimate pressure and temperature conditions. The procedure involves the input of the wt% chemistry of hornblende and plagioclase pairs assumed to be lying in equilibrium. Based on this information, this program provides a likely estimate based on a series of calculations to provide a constraint on temperature and pressure. Temperature estimates follow estimate procedures by Holland and Blundy, (1994); Blundy & Holland, (1990) while pressure estimates are given by Schmidt, (1992) and Anderson & Smith,

(1995). Given that hornblende and plagioclase are likely to be retrograde mineral features in these rock samples, the pressure-temperature conditions will only provide a minimum constraint on these estimates.

## **4.2. Whole Rock Major and Trace Elements**

Analytical techniques and analysis for whole rock major and trace element concentrations were analysed at Amdel Bureau Vista. Thirty two samples were cleaned, jaw crushed and milled with a Tungsten Carbide mill into a very fine powder (<425  $\mu\text{m}$ ). Samples were sent to Amdel Bureau Vista, Thebarton, South Australia for analysis. Laboratories work to documented procedures in accordance to ISO 9001 Quality Management Systems standard. Three standard samples were analysed to ensure reproducibility of the study, which includes JG-3, BHN2A and MNT2A. Major elements analysed include;  $\text{Al}_2\text{O}_3$  (0.01%),  $\text{CaO}$  (0.01%), Total Fe as  $\text{Fe}_2\text{O}_3$  (0.01%),  $\text{K}_2\text{O}$  (0.01%),  $\text{MgO}$  (0.01%),  $\text{MnO}$  (0.01%),  $\text{Na}_2\text{O}$  (0.01%),  $\text{P}_2\text{O}_5$  (0.01%),  $\text{SiO}_2$  (0.01%),  $\text{TiO}_2$  (0.005%) and Loss on Ignition (L.O.I).

### *4.2.1. Trace Elements*

Six samples were also analysed to use more precise measurements used in isotopic calculations. Methods involved mixing approximately 10g of sample powder with 1ml of binder solution (Poly Vinyl Alcohol) and pressed to form a pellet. This was allowed to dry in air and was heated for a further 1 to 2 hours in a 60°C oven to ensure that the pellet was completely dry before analysis. The samples were analysed using a Philips PW 1480 XRF Spectrometer, using several analysis programs covering suites of from 1 to 7 trace elements, with conditions optimised for the elements being analysed. The programs were calibrated against many (30 or more in some cases) local and international SRM's. The dual-anode Sc-Mo tube (operated at sufficient voltage to excite the Mo) and an Au tube were used for the analyses. Matrix corrections are made using either the Compton Scatter peak, or mass absorption coefficients calculated from the major element data. The extensive list of trace elements used in the analysis are reported in Table 2.

### 4.3. U-Pb Dating

Zircons obtained from samples SR-63, SR-6, SR-57 and SR-68H (see Table.1. for descriptions of samples), which involved garnet-rich and hornblende-rich charnockites, a clinopyroxene-bearing granite and a pink alkali granite from Ayyarmalai, were dated using U-Pb methods. Samples were washed, crushed with a dual jaw crusher and then separated with a meshed sieve to obtain a sand grain (79–300  $\mu\text{m}$ ) portion of the samples. Grains of zircons were obtained by panning out the heavy mineral portion of the grains and then scanned with a neodymium hand magnet to remove other minerals before being handpicked and mounted into epoxy resin blocks. These zircon mounts were then CL imaged using a Phillips XL-20 SEM with attached Gatan cathodoluminescence detector to determine and enhance any zonation or surface features of the zircon samples. U-Pb isotopic data were obtained using the Laser Ablation Inductively Coupled Plasma Mass Spectrometer (LA-ICPMS) in a He ablation atmosphere housed at the University of Adelaide. Standards Plesovich and BJWP (ca 720 Ma) were analysed simultaneously throughout the study to ensure reproducibility of the study. Laser pit diameter was 30  $\mu\text{m}$  and analysed to a typical total depth of 40–50  $\mu\text{m}$ .

U–Pb fractionation was corrected using the GEMOC GJ-1 zircon (TIMS normalisation data  $^{207}\text{Pb}/^{206}\text{Pb} = 608.3 \text{ Ma}$ ,  $^{206}\text{Pb}/^{238}\text{U} = 600.7 \text{ Ma}$  and  $^{207}\text{Pb}/^{235}\text{U} = 602.2 \text{ Ma}$  (Jackson *et al.*, 2004). A number of zircon grains were excluded from analysis due to small size. Zircon cores larger than 40  $\mu\text{m}$  in size were targeted, as well as some large metamorphic rims. In the data interpretation, a < 10% discordancy threshold was used for all grains analysed. Probability density plots have been constructed using Isoplot version 3.0 (Ludwig, 2003).

### 4.4. Whole Rock isotopic analyses

#### 4.4.1 Radiogenic Isotopes

Analytical techniques and analyses for whole rock Sm–Nd isotopic data follow those of Payne *et al.* (2006) and were performed at the University of Adelaide. Seven samples; including 5 samples from Ayyarmalai, 1 blank sample and 1 standard sample (GSWP#2) were spiked with a  $^{150}\text{Nd}$ – $^{147}\text{Sm}$

solution. HF was added to the sample in Teflon ‘bombs’ and evaporated. The samples were then oven-heated at 190°C for 5 days in HF in sealed Teflon bombs. The HF was then evaporated, with HNO<sub>3</sub> added shortly before samples were completely dry. 6 M HCl was added and samples were heated for 2 days at 160°C. REE were separated in Biorad Polyprep columns, and were further separated in HDEHP-impregnated Teflon-powder columns to isolate Sm and Nd. Nd was run on a Finnigan MAT 262 Thermal Ionisation Mass Spectrometer (TIMS) and Sm was run on a MAT 261 TIMS. The GSWP#2 standard gave a long term running average of  $0.511834 \pm 0.000018$  ( $2\sigma$ ,  $n = 96$ ) and  $0.512092 \pm 0.000016$  ( $2\sigma$ ,  $n = 164$ ) respectively. Epsilon values were calculated relative to a chondrite present day  $^{143}\text{Nd}/^{144}\text{Nd}$  value of 0.512638 and  $^{147}\text{Sm}/^{144}\text{Nd}$  value of 0.1966 (Goldstein *et al.*, 1984). Crustal residence ages relative to the depleted mantle ( $T_{\text{DM}}$ ) assume present day  $^{143}\text{Nd}/^{144}\text{Nd}$  value of 0.513114 and a  $^{147}\text{Sm}/^{144}\text{Nd}$  DM value of 0.222 (REEs were separated in Biorad Polyprep columns again to further separate out Sr using the HDEHP-impregnated Teflon-powder columns to isolate Sr and Rb, which was dried and run on a Finnigan MAT 262 Thermal Ionisation Mass Spectrometer (TIMS). Pb was analysed using similar methods through separation with columns and run on the TIMS.

#### 4.4.2. Stable Isotopes

Whole rock samples were analysed for oxygen isotopes by Professor Chris Harris at the University of Cape Town, Stable Isotope Laboratory. Powdered whole rock samples were weighed, approximately 10mg, and loaded into Ni reaction vessels and reacted with ClF<sub>3</sub> for > 3 hours. The O<sub>2</sub> gas produced was converted to CO<sub>2</sub> via a platinised carbon rod and yields of gas were measured to ensure that the reaction in each case was complete. The CO<sub>2</sub> gas was analysed using a Finnegan DeltaXP mass spectrometer in dual-inlet mode. Two aliquots of the internal standard MQ were analysed with each batch of 8 samples. The data for MQ were used to normalise the raw data to the SMOW scale. Further details of the analytical method can be found in Harris & Ashwal (2002). The  $\delta^{18}\text{O}$  values are reported in table 3d, these values have been reported as delta values relative to SMOW (Standard mean ocean water). The equation (3), converts the measured isotope ratios to  $\delta^{18}\text{O}$

values. A sample with a positive  $\delta$  value is enriched in  $^{18}\text{O}$  relative to SMOW and one with a negative value is depleted in  $^{18}\text{O}$  relative to SMOW.

$$(3) \quad \delta^{18}\text{O} = \left[ \frac{(^{18}\text{O}/^{16}\text{O})_{\text{sam}} - (^{18}\text{O}/^{16}\text{O})_{\text{SMOW}}}{(^{18}\text{O}/^{16}\text{O})_{\text{SMOW}}} \right] \times 10^3$$

## 5. RESULTS

### 5.1. Mineral Analysis

Representative mineral chemistry analyses are reported in Table 5a-f; the resulting oxide data has been converted to their relevant cation quantities for convenience. The analysis represents the dominant minerals from the main charnockite rock type assemblages; including a garnet rich charnockite (SR – 84) and a hornblende rich charnockite (SR – 57).

#### 5.1.1. Ayyarmalai Charnockites

##### 5.1.1.1. Garnet

Garnet porphyroblasts are quite variable in their chemistry (Table 5f). Garnets in the hornblende rich charnockite are dominantly enriched in almandine ( $\text{Fe}^{2+}$  rich garnet) and grossular (Ca rich Garnet), and to a lesser extent andradite ( $\text{Fe}^{3+}$  rich garnet) and spessartine (Mn rich garnet) i.e.  $\text{Alm}_{52.61 - 60.78}$ ,  $\text{Grs}_{11.2 - 34.4}$ ,  $\text{And}_{4.3-22.4}$ ,  $\text{Sps}_{1.5-14.3}$ ). Chemical zonations from core to rim appear to exist with enrichment of pyrope (Mg garnet) increasing towards the core i.e. Rim values  $X_{\text{Mg}}$  (1.2 – 3.33) to core values  $X_{\text{Mg}}$  (3.5 - 10.24). Other than that, there are no significant chemical zonations within the garnets and as well as this the various porphyroblasts have chemistry that is quite variable and inconsistent to be able to determine any definite zoning trends for this sample. Garnet porphyroblasts in the garnet rich charnockite are similar in composition to the hornblende rich charnockites with the exception of a higher concentration of pyrope.

### 5.1.1.2. Pyroxenes

Orthopyroxene and clinopyroxene are both present in the Ayyarmalai charnockites; with increased clinopyroxene occurring in the hornblende rich charnockites. The clinopyroxenes are associated with orthopyroxene sometimes preserved within orthopyroxene cores and others with ilmenite and ca-hornblendes. These clinopyroxenes are of the diopside-hedenburgite series and has lamellae textures when in the orthopyroxene cores. It is likely that the porphyroblastic clinopyroxenes were modified to diopside-hedenburgite by extensive fluid migration through the matrix. It can also be considered that the diopside-hedenburgite porphyroblasts with Ca-Al-amphibole cleavage overgrowths originally formed as a peak assemblage similar to that of the core clinopyroxenes but the composition was then altered during retrogression.

Orthopyroxene occurs as hypersthene (Fe,Mg rich) and is slightly enriched in Mn. Hypersthene in these charnockites occur in associate with hornblende, magnetite and ilmenite; more specifically hypersthene rims ilmenite and sometimes magnetite. There is no evidence of chemical zonation from core to rim of hypersthene porphyroblasts. Attempts to delineate whether orthopyroxene crystallised during igneous or metamorphic event is shown in Figure 6h; a plot with  $X_{Mg}$  vs  $X_{Al}$  of orthopyroxenes compiled from well known igneous and metamorphic charnockites which has indicated a differentiation trend (Santosh, 2010, submitted).

### 5.1.1.3. Retrograde Minerals (Amphibole, Plagioclase, Biotite, Symplectite)

Amphiboles are a retrograde mineral in the charnockite assemblage. These are enriched in calcium and aluminium with  $X_{Mg}$  varying from 0.08 – 0.24; which most likely resulted from the breakdown of clinopyroxene in the presence of garnet. The retrograde plagioclases associated with amphibole are enriched in albite ( $Ab_{36.4-62.7}$ ;  $An_{37.3-42.8}$ ) which complements the breakdown of Na-rich clinopyroxene with garnet. There is however no major chemical zonation existing from core to rim of hornblende and the chemical compositions are fairly consistent across both hornblende rich and garnet rich charnockite samples. Biotite occurs in close association on hornblende and generally symplectites

occur in partly as moats around hornblende- biotite clusters.

### 5.1.3. *P-T estimate (Charnockite)*

Hornblende-Plagioclase geothermometry provided a consistent pressure-temperature estimate likely to represent the retrograde conditions, at  $T= 745.1-754.3^{\circ}\text{C}$  and  $P=5.61-5.38\text{kbar}$  using Andersons (1996) calculation format. This is a strictly minimum estimate given that hornblende and plagioclase are retrograde features in these assemblages.

## 5.2. Whole Rock Geochemistry

### 5.2.1. *Ayyarmalai Charnockites*

Representative geochemical data of all rock types in the Ayyarmalai area are reported in Table 1. Charnockite mineralogies include garnet-rich ( $\text{SiO}_2$  53.9- 72.9%) and hornblende-rich ( $\text{SiO}_2$  66.3 – 74.5%) which plot on the normative Ab-An-Or ternary diagram as quartz monzonites, while the mafic enclaves ( $\text{SiO}_2$  – 45.1-57.6%) plot in the granodiorite field and the gneissic zones from the charnockite quarry ( $\text{SiO}_2$ -65.5-71.2%) in the granite field. With the variable silica contents, charnockites display (0.87-0.96) high Fe# (0.97-0.99), plotting as ferroan. In the Harker's binary diagram the major elements define linear trends (Fig. 5), and on the AFM triplot, trend from Calc-alkaline to tholeiitic in a straight line (Figure 6f) i.e. charnockites trend from Calc-alkaline to tholeiitic in a line, where the Ayyarmalai granite sits at the lowest part of the calc-alkaline field, then charnockites trend up in variably with the charnockitic gneisses into the tholeiitic field where it finishes with the restites.

With the exception of  $\text{K}_2\text{O}$ , concentrations for all major elements decrease with increasing silica for all the rock types. According to the ASI index (Figure 5j) the samples are divided into metaluminous and peraluminous varieties with the majority of the garnet rich charnockites plotting in the peraluminous field while the hornblende rich charnockites plot in the metaluminous field. These

charnockites plot in the Calc-alkalic to alkali-calcic field. They also plot in the A-type granitoid classification field.

Trace elements are also correlated with  $\text{SiO}_2$  (Figure 5k-r) for the variable charnockite varieties. Only Ba, La and Ce show notable scattering. The Ayyarmalai charnockite is rich in Ba and Sr, similar to high-Ba-Sr granitoids (Figure 6g; Rajesh & Santosh, 2004; Tarney & Jones, 1994). Ba contents are quite high (Ba 1500-2500ppm) while Sr is moderately low (Sr = 50-200ppm) whereas Ni and Cr contents are moderate (Ni = 7-19ppm and Cr = 10-40ppm). The Zr content is abnormally high (Zr = 300-2900ppm) with the very high Zr content existing in themafic enclaves. The REE contents are highly variable but generally characterized by high LREE contents ( $\text{La}_N = 367.85-59.95$ ) and display a moderate to low fractionated REE patterns ( $\text{La}_N/\text{Yb}_N = 25.06-4.3$ ) and no to slightly positive Eu anomalies. Charnockites from Ayyarmalai show depletion in Ti, Sr and enrichment in Pb, Th and Zr when normalised to primitive mantle (Figure 7b). The charnockites fall in the high-k calc-alkaline to shonshonite series i.e. they are highly potassic. Shows chondrite normalised plot trending across the dehydration zone which indicates no significant change in elemental composition from the granite- to the dehydration zone and back into the granite.

### 5.2.2. *Ayyarmalai Pink and Grey Granites*

The pink and grey granitoids from the Ayyarmalai hill can be differentiated in mineralogy by the presence of clinopyroxene (diopside – hedenburgite) in the grey granite. Silica content varies from 73.9-77.8%, with high Fe# (0.97-0.99), plotting as ferroan higher than the charnockites (fig.5h). According to the AFM ternary diagram, the Ayyarmalai granitoids show a typical calc-alkaline differentiation trend (Fig.6f). The Ayyarmalai granites are fairly divided into metaluminous and peraluminous varieties, so this doesn't provide a distinct field. The MALI plot shows that the rocks from the Ayyarmalai area plot in the Calc-alkalic to alkali-calcic field (Figure 5i). They also plot in the A-type granitoid classification field (Figure 6e).

The Ayyarmalai granites are low in Ba and Sr, similar to low Ba-Sr granitoids (Figure 6g; Rajesh & Santosh, 2004; Tarney & Jones, 1994) granitoids. Ayyarmalai granites normalised to the bulk continental crust (Figure not shown) show small depletion anomalies in Ba and Nb, significant depletion anomalies in Cs, Sr and Ti and enrichment peaks at Rb and Th.

The REE patterns are moderately fractionated ( $La_N/Yb_N = 20.05-6.01$ ) which don't significantly differentiate them from the charnockites. When normalised to primitive mantle (Figure 7b), the alkali granites are highly depleted in Sr, P and Ti and enriched in Pb, Ba, Th and U. Trace element plots show some strong trends against silica, where Zr, Ti, mg# and Ni decrease with increasing silica content while Rb, A/CNK,  $K_2O/Na_2O$  increase with increasing silica (Figure 5k-v). The Ayyarmalai granite however shows LREE enrichment ( $La_N = 340 - 57.22$ ), similar to the charnockites but does differ with a significant Eu depletion anomaly (Figure 7a).

### 5.3. U-Pb Zircon Geochronology

U-Pb analysis data has been presented in Table 4. Five different rock lithologies from Ayyarmalai were zircon dated using U-Pb methods including; hornblende rich charnockite (SR-57), garnet rich charnockite (SR-6), pink alkali granite (SR-68H), Grey granite (SR-63) and charnockitic Gneiss (SR-55).

#### 5.3.1. Charnockite Zircons (SR-6 and SR-57)

All zircon grains from the charnockite from Ayyarmalai quarry range from 50 - 400 $\mu$ m in size, they are subrounded to prismatic shaped, some contain xenocrystic cores as well as zoned, unzoned (or very weakly zoned) grains and convolute chaotic core textures (Figure 4c-d). Cathodoluminescent (CL) images show that most of the zircon grains very chaotic textures display, typical granulite facies zircons (Pidgeon *et al.*, 2000). Some domains evolve as marginal bands and as lobes that locally penetrate the interior of grains, locally they also form amoebic zones entirely enclosed in the centre of the grains. Many of the cores are characterized by distinct oscillatory zoning resembling the former magmatic zircon (Fig 4c-d). Dark rims are found on some zircon grains, although these tend to

parallel the earlier more luminescent bands and are interpreted to represent the last phase of zircon growth rather than a younger phase of new zircon. The Th/U ratios of the zircons from charnockites are generally slightly higher in the cores (Th/U = ~0.2-0.6) while the rim overgrowths have lower ratios (Th/U = ~0.08 – 0.1). This indicates a low Th and high U (diagnostic of metamorphic overgrowths) in the rims whereas the high Th, low U contents are diagnostic of magmatic zircons (Hoskin & Schaltegger, 2003). The possibility of two events is consistent with the relatively high concentrations of U, low Th/U, and the structureless nature of the rims in these samples which is consistent with a metamorphic origin for the rims of zircon. As well as this, relatively low concentrations of U, high Th/U, and oscillatory zoning in the cores is consistent with a magmatic origin for the cores of the zircon grains.

The analysed cores from SR-57 (hornblende-rich charnockite) zircons provided an upper intercept age of  $2652 \pm 27$  Ma and a lower intercept of  $1151 \pm 240$ Ma, MSWD = 3.5 (Figure 4d). The large overgrowths provided an upper intercept age of  $2509 \pm 40$  Ma and a lower intercept age of  $984 \pm 430$ Ma, MSWD = 3.5. Therefore two Discordia lines are interpreted for the spread of data and this is well represented in the Concordia Diagrams (Fig 4d). Smearing of data between the two populations of zircons are a likely cause for the high MSWD error. The core ages range from 2.5 – 2.68 Ga with varying ages in the layers in the oscillatory zoning. The large span of ages of metamorphic zircons from 2.2 – 2.5 Ga indicates either a prolonged metamorphic event of significant Pb loss during metamorphism.

Analysed cores and rims from SR-6 (garnet rich charnockite) have provided only one Discordia line with an upper intercept age from the cores of the zircons being  $2684 \pm 36$  Ma and a lower intercept age of  $1584 \pm 340$  Ma, MSWD = 2.8 (Figure 4c). The overgrowth rim age could not be determined due to the high degree of metamictisation causing a high discordancy that was without the 10% threshold.

### 5.3.2. Ayyarmalai Granites (SR-68H and SR – 63)

All zircon grains from the charnockite from Ayyarmalai quarry range from 70 - 200 $\mu$ m in size and have subrounded to prismatic to pyramidal elongated shapes. CL images show some grains contain xenocrystic cores as well as zoned, unzoned (or very weakly zoned) grains and convolute chaotic core textures (fig 4a-b). Many of these zircons have complex oscillatory zoning at the cores while others display metamictisation. Large highly luminescent rims exist around the cores. The Th/U ratios of the zircons from granites are generally slightly higher in the cores (Th/U = ~0.2-0.8) while the rim overgrowths have lower ratios (Th/U = ~0.2 – 0.3). This indicates a low Th and high U (diagnostic of metamorphic overgrowths) in the rims whereas the high Th, low U contents are diagnostic of magmatic zircons (Hoskin & Schaltegger, 2003), suggesting two separate events similar to the charnockite samples.

The analysed cores from SR-68H (Pink alkali granite) zircons provided an upper intercept age of 2638  $\pm$  47 Ma and a lower intercept of 570  $\pm$  1200Ma, MSWD = 3.5 (Figure 4b). The large overgrowths provided an upper intercept age of 2465  $\pm$  56 Ma and a lower intercept age of 521  $\pm$  1500Ma, MSWD = 4.0. Therefore two Discordia lines are interpreted for the spread of data and this is well represented in the Concordia Diagrams (Fig 4b).

The analysed cores from SR-63 (Grey granite) zircons provided an upper intercept age of 2677  $\pm$  90 Ma and a lower intercept of 1351  $\pm$  680Ma, MSWD = 8.4 (Figure 4b). The large overgrowths provided an upper intercept age of 2567  $\pm$  37 Ma and a lower intercept age of 1112  $\pm$  460Ma, MSWD = 0.83. Therefore two Discordia lines are interpreted for the spread of data and this is well represented in the Concordia Diagrams (Fig 4b). Similarly to the charnockites there is a high degree of smearing of data between the two populations of zircons due to Pb loss in the older zircons during metamorphism; a likely cause for the high MSWD error. However, the most important feature is that both the granites and the charnockites contain similar core-rim structures, overgrowth patterns and ages.

## 5.4. Isotopic Data

### 5.4.1. Radiogenic Isotopes

Mineral-whole rock Sm-Nd, Rb-Sr and Pb-Pb dating of the charnockite from the Ayyarmalai location (Fig.1) is listed in table 3a-c respectively. Further additional samples are reported from other areas relating to Eastern Gondwana i.e. samples from Palghat-Cauvery Shear System, Southern Granulite Terrain, Northern Granulite Terrain, Dharwar Craton, Madagascar, Sri Lanka and East Antarctica (See References in Tables 2a-b).

#### 5.4.1.1. Sm-Nd

Three of the Ayyarmalai charnockite samples analysed (SR-1, SR-57 and SR-84) yielded  $\epsilon_{\text{Nd}}(0)$  values which range between -25.15 to -33.14. The two Ayyarmalai granite samples analysed (SR-68H and SR-861) also range from -25.15 – 32.4. The core ages represented in the zircons of these samples were around 2.65Ga while the metamorphic overgrowths are consistent with a granulite facies metamorphic that occurred in the NGT (~2.5 Ga) (Rajesh & Santosh, 2004; Rajesh, 2008). Therefore, the  $\epsilon_{\text{Nd}}(2.65 \text{ Ga})$  values of the charnockites range from -2.97 to -4.57 and  $\epsilon_{\text{Nd}}(2.5 \text{ Ga})$  range from -4.7 to -4.57 (Table 3a). The two alkali granite samples had  $\epsilon_{\text{Nd}}(2.65 \text{ Ga})$  values range from -3.8 to -5.31, while the  $\epsilon_{\text{Nd}}(2.5 \text{ Ga})$  range from -5.39 to -6.86. An errorchron age for the charnockites and granites combined of  $2515 \pm 620 \text{ Ma}$  is calculated based on the Sm-Nd data (initial  $^{143}\text{Nd}/^{144}\text{Nd}$  of  $0.50910 \pm 0.00049$ , MSWD = 1.7) (Figure 9a). The  $^{147}\text{Sm}/^{144}\text{Nd}$  ratios of all the samples lie within the range of 0.1081 – 0.134. Although the error is quite large, these points all lie in line with each other and correspond with the crystallisation ages of these rocks, indicating possible co-magmatism. The  $T_{\text{DM}}$  (Depleted Mantle) model ages range from 2890 – 3090Ma in these samples, ages significantly older than the crystallisation ages. Results are plotted in the  $\epsilon_{\text{Nd}}$  evolution diagram (Figure 8a).

#### 5.4.1.2. Rb-Sr

Obtained Rb-Sr data and calculations are reported in Table 2b on samples from Ayyarmalai. The calculation of the initial ratio ( $^{87}\text{Sr}/^{86}\text{Sr}$ ) can be used to compare with the standard value of 0.706, a

number that represents that anything lower than this the rock was derived from partial melting of the mantle. Four samples from Ayyarmalai have initial ratios calculated at 2.5Ga of between 0.7019 and 0.7344. Sample SR-861 shows an impossible initial ratio of 0.5598 which is probably due to post Archaean alteration. An errorchron age for the charnockites of  $2536 \pm 1200$  Ma is calculated based on the limited Sr-Rb data (Initial  $^{87}\text{Sr}/^{86}\text{Sr} = 0.7 \pm 1.5$ , MSWD = 11.7) (Figure 9b).

#### 5.4.1.3. Pb-Pb

The  $^{207}\text{Pb}/^{206}\text{Pb}$  isochron, reports an errorchron age of  $3496 \pm 1100$  Ma, MSWD = 4.3. This is significantly older than the predicted Nd model ages, therefore this age estimate has a significant error due to the limited number of samples analysed and the significant uranium loss that is likely to have occurred since the Archaean age.

### 5.4.2. Stable Isotopes

#### 5.4.2.1. $\delta^{18}\text{O}$ isotopes

Whole-rock oxygen isotope analysis was performed on samples that were to represent a traverse from Hornblende rich charnockite – garnet rich charnockite – grey granite – dehydration zone – pink Ayyarmalai granite. The hornblende rich charnockites shows an abnormally low  $\delta^{18}\text{O}$  value of -0.11 ‰, while the rest of the samples have increasingly higher  $\delta^{18}\text{O}$  values, with none higher than 5.4%. The range of  $\delta^{18}\text{O}$  values typical for igneous rocks like between +6 and 15%. Garnet rich charnockites have  $\delta^{18}\text{O}$  values that lie closer in to the typical igneous rocks range, whereas the dehydration veins, granites and hornblende rich charnockite have very low  $\delta^{18}\text{O}$  values. Low  $\delta^{18}\text{O}$  values can indicate that these rocks crystallised from low  $\delta^{18}\text{O}$  magma (Valley *et al.*, 1986; Taylor *et al.*, 1991; Hoefs, 1980), or most likely, the protolith had its  $\delta^{18}\text{O}$  lowered by exchange with meteoric water prior to peak metamorphism. On determination of  $\delta^{18}\text{O}$  of Quartz for three samples which are almost the same (slightly higher) than the whole rock values determine the samples were in O-isotope equilibrium at high-temperature. This suggests that the low  $\delta^{18}\text{O}$  values were a part of the high-*T* mineral assemblage (Valley *et al.*, 1986; Taylor, 1987; Taylor *et al.*, 1991; Hoefs, 1980).

## 6. DISCUSSION

### 6.1. Petrographic & Geochemical Interpretation

Sampling for this study has essentially incorporated as many of the mineralogical varieties in the field area. Field and petrographic studies clearly delineate garnet-rich, intermediate hornblende-rich charnockites as well as low silica hornblende-rich mafic varieties within the Ayyarmalai charnockite massif. Based on the differences between the major and trace elements compositions, strong linear trends in harker diagrams and the REE patterns, the combined data suggests that the charnockites and alkali granites at Ayyarmalai formed from the same parent magma. This involves the mafic samples that trend down towards the intermediate charnockites and charnockite gneiss zones and finishes at the silica, K-rich granites. The low silica rocks have the highest REE but with no negative Eu anomaly and then progressively moving towards the alkali granite is the development of a significant Eu anomaly (Figure 7a). Given that these hornblende rich mafic samples have similar iron concentrations as the other samples (Figure 5b), low Cr, anomalously high Zr and occur as blocks/blebs within the charnockite quarry walls it's not likely that these mafic samples are derived from primitive mafic magma. One possibility of the origin of these mafic charnockites is that they are hornblende-pyroxene-Fe-Ti oxide-plagioclase adcumulates that when separated from the melt resulted in the intermediate charnockite composition this driving crystallisation towards the alkali granite. This is consistent with the nature of these mafic charnockites that is, brought out in blocks/blebs in the waxy green-grey homogenous charnockites. If this is the case, this would put the parent magma at a composition between the mafic cumulates and intermediate charnockites.

The dehydration zones in the grey granite at the western base of the pink alkali granite have almost identical geochemical (major and trace) concentrations as the grey granite. While several attempts were made to obtain the most representative samples in the area, no orthopyroxene was identified in these selvages. These dehydration veins contain a simple assemblage of quartz, plagioclase, feldspar (in the form of microcline) and ilmenite/magnetite. Unless non-sampled selvages exist in the field that contain orthopyroxene in their assemblages it suggests that these veins are not charnockites (or "incipient" charnockites representing an early stage of charnockite formation

initiated from movement of high pressure CO<sub>2</sub> rich fluids travelling through channels and fractures in the surrounding rock) and do not represent the generation of charnockites through metamorphic mechanisms. Interestingly, these selvages still encompass that waxy green-grey colour that is a feature of many charnockites. It is interesting to note that the waxy green colour was still produced regardless and deceptively looks almost identical to incipient charnockites such as at Kalbbadurga (Bhattacharya & Sen, 2000). This now requires thin section microscopy and mineral chemistry analysis to confirm in other cases whether orthopyroxene is present in these veins.

The other dominant feature of these charnockites and granites from Ayyarmalai is the alkali ferroan A-type signature that is widely reported in the literature (Figure 6e) (Whalen *et al.*, 1987; Eby, 1990; Chappell & White, 1992; Frost *et al.*, 2001). A-type granitoids (i.e. anorogenic granitoids) are those that intrude into non-orogenic settings, are generally higher in SiO<sub>2</sub> (~77%), alkalis, Fe/Mg, halogens (F and Cl), REE, Ga/Al, Zr, Nb, Ga, Y and Ce and lower in trace elements compatible in mafics (Co, Cr, Ni) and feldspars (Ba, Sr) than I-types (Whalen *et al.*, 1987; Eby, 1990). However, post orogenic granitoid compositions range from strictly peraluminous S-types, to metaluminous I-types and hybrids, to those with A-type chemical characteristics; therefore the discriminate tectonic setting with A-type granitoids can be deceiving. The R<sub>1</sub>-R<sub>2</sub> diagram plot shown in Figure 10, shows that the majority of the samples from Ayyarmalai share similarities with a post orogenic and syn-collision geodynamic setting. Though these samples from Ayyarmalai are regarded as A-type, within plate granites the geochemistry suggests that these may be ascribed to a post-orogenic geodynamic setting at the time of emplacement. Alternatively, a two stage melting model, involving basaltic underplating proposed by Rajesh (2008), can result in the formation of A-type calc-alkaline charnockite and alkali A-type granites from the Nilgiri and Madurai blocks. Trends in the geochemistry indicated in Figure 5, show some similarities with the Munnar granite from the Madurai Block which would make this model plausible.

This study favours the early crystallisation of orthopyroxene in granitic melts like charnockites and lacks metasomatic alteration. This is similar to cases when associated with anorthosites and mangerites within AMCG suites (Esmlie, 1991; Duchesne & Wilmart, 1997; Markl *et al.*, 1989).

Ayyarmalai is likely to exist as part of an AMCG suite and to determine this identification as well as collection of U-Pb zircon and monazite, Sm-Nd and geochemical data of anorthosites and mangerites surrounding Ayyarmalai would help find possible relationships.

## **6.2. Timing & Significance of Charnockite and Feslic Magmatism in the PCSS**

Rocks from the PCSS have displayed multiple ages of 2.5 Ga, 1.8 Ga and 0.55 Ga. These have been attributed to date the crystallisation age, detrital zircons in metasediments and a metamorphic event respectively. The 0.55 Ga metamorphic event is widely reported in the literature as relating to the final stages of Gondwana accretion resulting in a granulite facies metamorphic event. The Ayyarmalai Pink Granite (2.67-2.63 Ga) has similar ages to the charnockite (i.e. 2.68-2.65 Ga) with the same overgrowth rims interpreted as the age of a granulite metamorphic event (2.45-2.5 Ga). This again indicates that these two rock types formed at the same time, again consistent with these rocks being co-magmatic. Curiously, the U-Pb zircon ages of the overgrowth rims suggest a granulite facies metamorphic event at 2.45-2.5 Ga. No evidence of the 0.55 Ga metamorphic event is evident in these Ayyarmalai A-type charnockites and alkali granites. Given this, Raith *et al.* (2010), recently presented U-Pb detrital zircon data from corundum bearing leucosomes from Kupprattipatti, west of Ayyarmalai. These detrital zircons had inherited concordant domains between 2502 and 1992Ma, a discordia with upper and lower intercept ages of  $2481 \pm 37$  and  $532 \pm 63$  Ma and a concordant age of  $529 \pm 9$ Ma. This presents a dilemma as to why the charnockites and granites from Ayyarmalai do not contain these Cambrian age overgrowths while leucosomes analysed at a small town only a few kilometres from Ayyarmalai do. Further zircon dating and structural mapping in the area would be required to better constrain the age of events and any structural barriers that occur between these areas.

The 2.45-2.5Ga metamorphic overgrowth rims do not correlate with ages in the SGT, however it does correlate with a widespread granulite thermal event synchronous with tectonism in the adjacent Salem Block (or NGT) occurring at 2.5-2.55Ga. The zircons from the charnockite and the pink granite

from Ayyarmalai also show very similar age structures to those from granites in the Madras, Salem & Nilgiri blocks, which are north of the PCSS. Most of these plutons have zircon core ages of 2.9 - 2.6Ga and are surrounded by metamorphic rims of 2.4-2.5Ga (Santosh *et al*, 2003; Vinogradov *et al*, 1964). Like the NGT, Ayyarmalai also lacks any of the Neoproterozoic-Cambrian metamorphic overgrowths (Clark *et al* 2009). This suggests that the NGT represents reworked Dharwar Craton as suggested in Collins *et al* (2010) or primary, late stage growth of the craton. Some U-Pb zircon data has suggested there may have been a metamorphic event dated at ~2.5Ga in the Dharwar Craton representing a magmatic event dominated by voluminous granite magmatism. The Ayyarmalai Pink granite displays similar geochemical and petrological characteristics of late Neoproterozoic granites, however, these geochronological results conclusively show them to be Archaean. Consideration of a late Archaean magmatic and tectonic event in the Dharwar craton has been explained by a rising megaplume that produced such granitoids as the Closepet and Bangalore Granitoids (Peucat *et al*, 1993; Choukroune *et al.*, 1995). Given that samples from Ayyarmalai display similar geochemical characteristics with the Dharwar craton rather than the SGT this origin needs to be considered. This involves a rising plume into a mature crust which causes softening in the crust, inverse diapirism and thus induces metamorphism. However, there are certain features of a plume that are inconsistent with observations from Ayyarmalai data. For instance, plume magmatism has been known to display more juvenile Nd magmatic signatures (sometimes with small crustal signatures) and the results from Ayyarmalai suggest a much evolved source with a large crustal input. This is illustrated in the Closepet and Bangalore Granitoids and on comparison between the isotopic compositions between them and Ayyarmalai; the granitoids do not appear to be correlated. As well as these differences in composition between the two rock types at Ayyarmalai lying in such close association is unlikely to occur, whereby a plume might produce a much more homogeneous rock type over a larger area. Therefore, a plume model in the case of Ayyarmalai appears to be unlikely.

The other possibility in relation to the ages obtained from granites within the PCSS relates to the evolution of Gondwana. As Gondwana formed, the Mozambique Ocean closed and its suture was identified in Madagascar, known as the Betsimisaraka suture (Collins & Windley, 2002; Collins *et al.*,

2007). Collins *et al* (2007) suggested that the PCSS is an ideal candidate for the continuation of this suture due to the correlation of tectonic units; however this is still often disputed (Shackleton, 1996; Collins & Windley, 2002; Meert, 2003). The Cambrian metamorphic ages (~500 Ma) found in several places along the PCSS also exist along the Betsimisiraka suture belt (Collins *et al.*, 2003); suggested to correspond with the closure of the ocean and subsequent collision of India with Azania (called the Malagasy Orogeny ~540-520Ma) (Collins & Pisarevsky, 2005). Collins *et al* (2002) suggested that the Antananarivo block of Madagascar, south of the Betsimisiraka suture has <2.6 Ga rocks exposed which may correlate with rocks from the Madurai Block, the Karur-Kambam-Painavu-Trichur shear zone (KKPT) and PCSS. The Antananarivo Block is separated from the Antongil Block (suspected to be the Dharwar craton) by a paragneiss belt that is highly deformed and contains ultramafics and some Neoproterozoic sediments (Collins *et al*, 2002; Collins & Windley, 2006). If samples from Ayyarmalai did strongly correlate with those from the Antananarivo block, it would suggest that the microcontinent Azania extends to encompass these areas. It would also suggest that there is possibly a belt of pre-Neoproterozoic crust that extends from the northern Madurai Block (separated from metamorphosed Dharwar craton by the PCSS) that extends through the Antananarivo Block. Given that charnockites and granites from Ayyarmalai do not contain evidence of the Neoproterozoic-Cambrian metamorphic age Andean-style plate boundary, it may also suggest that the suture zone actually cuts south of the PCSS and that this shear zone represents the northern limit of the Neoproterozoic and early Cambrian magmatism, metamorphism and orogenesis.

### **6.3. Protolith and Crustal Evolution in the PCSS**

In discussion of the reconstruction of eastern Gondwana, it is important to compare the isotopic composition of the Ayyarmalai charnockites and granites with potentially adjacent terrains in the supercontinent. As Pb data are scarce and Rb-Sr is highly sensitive to fractionation, Sm-Nd isotope data presented in this study are compared with data from the Dharwar Craton, NGT, PCSS, SGT, East Antarctica, Sri Lanka and Madagascar (Table 3a; Figure 8a).

The charnockites and granites from Ayyarmalai have model ages between 2.8 – 3.09Ga, ages that are slightly older than their crystallisation ages. The proposition that the charnockites and granites are co-magmatic are confirmed by the similar model ages which clearly verify the crystallisation ages (Figure 9a). The negative  $\epsilon\text{Nd}(t)$  values (between -4.7 to -6.86) and older Archaean  $T_{\text{DM}}$  model ages suggest that these rocks could be generated (i) either by melting of a contaminated depleted mantle source; (ii) by melting of an enriched mantle source (not solely derived from depleted mantle and are likely to be contaminated), or (iii) through contamination of mafic magmas from the depleted mantle and contamination by crust with older  $T_{\text{DM}}$  values (>2.8-3.09 Ga). Figure 8a indicates that the charnockites and granites from Ayyarmalai correlate with charnockites from the NGT given the similar Nd characteristics and zircon U-Pb crystallisation ages (Bhaskar Rao *et al.*, 2003; Meißner *et al.*, 2002); however these samples have a more juvenile magma input. As well as this, Figure 8; 9d, suggests that the rocks from Ayyarmalai fall in the field of TTG basement of the Dharwar craton which suggests a possible source of crustal contamination. The samples also closely relate to the ~2.55 Ga granites that intruded the Dharwar craton i.e. Late Archaean K-granites from the AB suite, Bangalore granites and some TTG gneisses (Jayananda *et al.*, 2000; Rickers *et al.*, 2001). Based on limited published data of basement gneiss in the Antananarivo block, the data suggests that this is not a likely source for crustal contamination of the Ayyarmalai samples (Kroener, 2000). This further supports the possibility that the Ayyarmalai consists of metamorphosed Dharwar Craton. Given Sm-Nd data is limited in the Antananarivo block; further data collection would prove beneficial to support this theory.

The granite samples from Ayyarmalai analysed for  $\delta^{18}\text{O}$  could indicate features about the type of magma these rocks crystallised from. Granites that exhibit near-equilibrium oxygen isotope fractionations for constituent minerals are characterized by magmatic O-isotopic compositions (~+6-8‰), however this is not the case with the Ayyarmalai granitoids as they are lower than the magmatic compositions. The Ayyarmalai granitoids all have low  $\delta^{18}\text{O}$  whole rock values of -0.11 to +4.4 indicating contamination with reworked sediments that are mixed with meteoric water (not a viable mechanism on mass balance grounds). However, given the high amount of crustal contamination in

these rocks of Archaean age ( $T_{DM}$  model ages of 2.7-3.04 Ga), this may suggest that the low  $\delta^{18}O$  source comes from the Archaean crustal block that the magma intruded and mixed with. The suggestion from this study that the intermediate charnockite crystallised orthopyroxene early is favoured by contamination of mafic mantle derived melts with siliceous crustal rocks; these values are supported by the  $\delta^{18}O$  values. In this case, possible scenarios include involvement from the Dharwar Craton as suspected in this study as the crustal contamination source given its similar protolith age. Alternatively, this signature may be related to the Antananarivo Block of Madagascar where it is proposed that the Betsimisiraka Suture zone just above the Antananarivo Block is a continuation of the Palghat-Cauvery Shear System in which where these samples were taken (Figure 11; Collins & Windley, 2002; Collins *et al.* 2007). However, the Nd model ages of Ayyarmalai do not appear to correlate with the Antananarivo Block but instead do correlate with the adjacent Northern Granulite Terrain and average Dharwar Craton basement.

Low  $\delta^{18}O$  values have been widely associated with subsolidus hydrothermal alteration for several igneous rocks worldwide (Criss & Taylor 1986; Harris & Ashwal, 2002). Granites that exhibit near-equilibrium oxygen isotope fractionations for constituent minerals are characterized by magmatic O-isotopic compositions ( $\sim +7\text{‰}$ ), however this is not the case with the Ayyarmalai granitoids as they are lower than the magmatic compositions (Valley *et al.*, 1986; Taylor, 1987; Taylor *et al.*, 1991; Hoefs, 1980). The Ayyarmalai granitoids all have quite low  $\delta^{18}O$  whole rock values of  $-0.11$  to  $+4.4$ . It is therefore necessary to establish whether the low  $\delta^{18}O$  values of the A-type Ayyarmalai charnockites and granites reflect the composition of the original magmas, or result from subsequent fluid-rock interaction. To establish this, it is rendered necessary to analyse the  $\delta^{18}O$  of separated minerals (not analysed in this study) from the samples to determine equilibrium; this would indicate if in fact the magma had the low  $\delta^{18}O$  signature. In this case, low  $\delta^{18}O$  values imply that either this is a characteristic of the source, was acquired during the evolution of the magma or was created through mixing with or assimilation of material that contained very low  $\delta^{18}O$  values (Harris & Ashwal, 2002). A likely scenario for these rocks would be a large high-temperature exchange with water at some stage in the protolith history, or sometime prior to peak metamorphism.

Given the limited extent of oxygen isotope data obtained from adjacent terranes, it would be useful for future research to compare this data with whole rock and mineral oxygen isotope data collected from the Dharwar craton, the Southern Indian Granulite Terrain and the Antananarivo and Antongil blocks of Madagascar.

## 7. CONCLUSION

Several interesting conclusions can be made about the evolution of the Ayyarmalai A-type charnockite-granite association:

- (1) The crystallisation age of the charnockites (2.68-2.64Ga) and granites (2.63-2.67Ga) from the south eastern PCSS are Archaean and depict a granulite facies metamorphic event occurring at 2.45-2.5Ga.
- (2) Strong co-linear trends in Harker diagrams, similar Nd model ages and U-Pb zircon ages and Nd errorchrons strongly suggest that the Ayyarmalai A-type Charnockite-Granite have experienced the same Nd evolution history and are co-magmatic.
- (3) The lack of orthopyroxene in the dehydration zones would suggest that the Ayyarmalai charnockites were not generated from CO<sub>2</sub> fluxing, and thus favours early crystallisation of orthopyroxene.
- (4) Nd isotopic values suggest the protolith is late Archaean in age (2.9-3.09 Ga) which have similarities with isotopic data from Dharwar Craton. However, similarities also exist with the Antananrivo Block of central Madagascar that was suggested as an extension of the Madurai Block by Collins *et al.* (2007).
- (5) Oxygen isotopic data suggests that the protolith had its  $\delta^{18}\text{O}$  lowered by exchange with meteoric water prior to peak metamorphism.

- (6) Geochemistry suggests a late syn to post tectonic setting (possibly post collisional). A two stage model of basaltic underplating combined fractional crystallisation with partial crystallisation may account for the varying compositions at Ayyarmalai.

## 8. ACKNOWLEDGMENTS

I would like to thank the Australian Government for supporting this work through an Australia-India Strategic Research Fund Grant. A huge thank you to my supervisors John Foden and Alan Collins for your endless knowledge and wisdom on the subject of rocks. Many thanks to Santosh and Chetty for the most welcomed assistance and hospitality in India and Alan for ensuring a smooth transition into a new country (and putting up with my inability to tolerate chilli). Thank you to William Teale and Vaddi Venkatasivappa for being my main field buddies and also Diana, Jade, Libby and Mohanty (India wouldn't have been the same without you guys). A massive thank you to Professor Chris Harris from the University of Cape Town for your valuable assistance with analysing my samples at short notice for oxygen isotopes and even when they couldn't be done in time still did them in the name of science. Your knowledge and wisdom on the topic was greatly valued and appreciated. Thank you to Justin Payne and Ben Wade for all the help and guidance in the labs. Finally, thanks to all the honours students, what a great year!

## 10. FIGURE CAPTIONS

**Figure 1a).** A geological diagram of Gondwana after Meert, 2010. The diagram show the the locations of continents arranged in the supercontinents, orogens. The fields in yellow depict Eastern Gondwana and the fiels in blue depict the arrangement of Western Gondwana.

**Figure 2. (a)** Simplified geological sketch of the Southern Granulite Terrain, south India (modified from Tomson *et al.*, 2006) showing major geological domains: Archaean and Neoproterozoic granulite blocks, the latter comprising Madurai Block (MB) and Trivandrum Block (TB), Cauvery Shear Zone system (CSZ), the Western and Eastern parts of Dharwar Craton (WDC and EDC). Abbreviations for charnockite massifs: Coorg (C), Biligiri Rangan (BR), Malai Mahadeva (MM), Shaveroy (SH), Pallavaram–Madras (MA), Nilgiri (NG), Kollimalai (KM), Palani–Kodaikkanal (KK) and Cardamon (CA). Major shear zones include: Moyar (Mo), Bhavani (Bh), Mettur (Mt), Salem–Attur (S–At), Gangavalli (Ga), Palghat–Cauvery (Pa–Ca), Karur– Oddanchatram (KOSZ), Karur–

Kambam–Painavu–Trichur (KKPT) and Acharnkovil (ASZ). **(b)** A simplified geological map of the field region (modified after Raith *et al.*, 2010). **(c)** A geological map of the field site at Ayyarmalai showing lithological boundaries, structural features and sample locations.

**Figure 3:** Hand specimen photos from Ayyarmalai: (a) A massif charnockite showing the black-grey-green appearance of a charnockite. (b) Garnet rich charnockite. (c) Dehydration zones occurring in a surrounding rock of grey granite characterized by red-feldspar, quartz, plagioclase, biotite and clinopyroxene. (d) A charnockitic gneiss zone showing individual prophyroblasts indicating south side up movement. (e) Pink granite with hornblende defining a lineation. (f) The boundary between the grey granite and pink alkali granite at Ayyarmalai. (g) Mafic charnockite with a quartz grain containing purple Amethyst. (h) Massif charnockite at Ayyarmalai quarry with zones of mafic patches/blebs. (i - q) Thin section photos (1cm = 10 $\mu$ m) showing relationships of minerals: i = hornblende rich charnockite, j = hornblende rich charnockite, k = hornblende rich charnockite, l = garnet rich charnockite, m = diopside with a corroded core in the grey granite in PL, n = diopside with a corroded core in the grey granite in XPL, o = Hornblende rich charnockite, p = Convolute textures in the pink granite, q = Granite dominated by microcline as the dominant feldspar, r = Convolute textures in hornblende rich charnockite. See text for further discussion.

**Figure 4:** a-d, Samples SR-63 (Grey Granite), 68H (Pink Alkali Granite), 57 (Hornblende rich Charnockite) and 6 (Garnet rich Charnockite) showing U-Pb Concordia diagrams and CL images of individual zircons in samples with their relevant analysed ages.

**Figure 5:** a-j: Harker Diagrams i.e. major elements vs SiO<sub>2</sub>. Shaded areas represent Massif charnockite compositions taken from the Palghat-Cauvery Shear System in the Northern Central Madurai Block area (Tomson *et al.*, 2006). Apatite and Titanite geotherms follow that of Watson and Harrison (1984) LOI = Loss on ignition. (h) Fe<sup>2+</sup>/(Fe<sup>2+</sup>+MgO) plot, shaded fields represent calc-alkaline granitoids and alkali A-type granitoids (Bryant *et al.*, 1999; Eby, 1990). (i) A MALI Plot. (j) An ASI plot showing the fields where metaluminous and peraluminous granites fall. (k-r) Trace elements vs SiO<sub>2</sub>.

**Figure 6:** Discrimination Diagrams: (a) A K/Rb vs. K<sub>2</sub>O plot, (b) Rb vs Sr plot, the field represents typical mantle values. (c) A Th/U vs La/Th diagram with shaded zone representing typical values of igneous rocks and directions where U or Th loss occurs. (d) An-Ab-Or diagram showing the Ayyarmalai charnockite composition in terms of normative An-Ab-Or. (e) A-type discrimination diagram showing the domains where I, S and A-type granites typically fall (Whalen *et al*, 1987). (f) An AFM diagram showing calc-alkaline and tholeiite series trends (Irvine and Barager, 1971). (g) A Rb-Sr-Ba triplot showing two distinct types of granitoids i.e. a low Ba-Sr Granitoid and a high Ba-Sr Granitoids. Fields of Low Ba-Sr Granitoids are from Fowler *et al* (2001), while High Ba-Sr granitoids are from Tomson *et al* (2006). (g) X<sub>Al</sub> vs X<sub>Mg</sub> plot comparing orthopyroxenes from metamorphic dehydration zones with orthopyroxenes that are clearly igneous. Data compiled by Santosh (2010) submitted.

**Figure 7.** Chondrite-normalised REE patterns (Sun and McDonough, 1989) incorporating all the rock types (b) Primitive mantle normalised REE patterns (Sun and McDonough, 1989).

**Figure 8.** Isotope Plots (a) An  $\epsilon$ Nd vs time (Ga) plot of Ayyarmalai samples compared with samples from Sri Lanka, Plaghat-Cauvery Shear system, Madagascar, East Antarctica, Dharwar Craton, Northern Granulite Terrane, Madurai Block. Shaded domains represent basement of the Dharwar craton and Madagascar.

**Figure 9.** (a) <sup>143</sup>Nd/<sup>144</sup>Nd vs <sup>147</sup>Sm/<sup>144</sup>Nd plot. (b) <sup>87</sup>Sr/<sup>86</sup>Sr vs <sup>87</sup>Rb/<sup>86</sup>Sr plot. (c)  $\epsilon$ Nd vs <sup>87</sup>Sr/<sup>86</sup>Rb plot, shaded area represents a wide range of basement values of the TTG Gneisses of the Dharwar Craton.

**Figure 10.** A tectonic discrimination plot, R1-R2 diagram model from Bachelor & Bowden, (1985) showing Ayyarmalai samples dominantly plotting in a post-orogenic field.

**Figure 11.** The proposed continuation of Azania into southern India (after Collins *et al*. 2007) where the continuation of the PCSS could be the Betsimisiraka suture in Madagascar. Abbreviations: PCSS = Palghat-Cauvery shear zone; KKPT = Karur-Kamban-Painavu-Trichur shear zone; MB= Madurai Block; TB= Trivandrum Block.

Table 1. Lithological descriptions, structural features and GPS localities of rock samples from Ayyarmalai, Tamil Nadu, Southern India.

Sample	Lithology	Structure	Locality	Longitude	Latitude	Image
SR-1	Massif fine grained, equigranular charnockite consisting of dark smoky coloured quartz, grey feldspars, brown weathered opx and possibly some cpx.	F 70/238	Quarry 1	10°52'32.8"N	78°22'25.5"E	
SR-2	Light Pink, equigranular and medium grained granitic composition rock. It has abundant quartz 45%, K-feldspar 40% and 10% black minerals which appears to be hornblende? Some of the black mineral specs are magnetic indicating the presence of Magnetite.	-	Western base of Ayyarmalai	10°52'30.4"N	78°22'45.9"E	
SR-3	Divided sample -one side blocky quartz vein and other is pink felsic granite with same lithology as SR-2	-	Western base of Ayyarmalai	10°52'30.4"N	78°22'45.9"E	
SR-4	Large pegmatite vein which cross cuts folding in the felsic granite, black dark veins run through the centre of the pegmatites which consist of magnetite.	-	Western base of Ayyarmalai	10°52'30.4"N	78°22'45.9"E	
SR-6	A light green-grey coloured garnet bearing charnockite, not as dark as the majority of samples in quarry.	-	Quarry 1	10°52'31.1"N	78°22'24.1"E	
SR-9	Grey-pink quartz, k-feldspar, biotite, mafic minerals hard to distinguish. Sample taken from gneissic zone within the quarry.	-	Quarry 2	10°52'31.8"N	78°22'24.0"E	
SR 50(1)(2)	Charnockite enveloped by coarse hornblende and quartz rich, glossy zones. Possibly a restite? (1) is the hornblende rich zone (2) is charnockite.	-	Quarry 3	10°52'26.1"N	78°22'26.2"E	
SR-51	Fine grained massif charnockite	-	Quarry 3	10°52'26.1"N	78°22'26.2"E	
SR - 52	Pegmatite Vein - K-feldspar, quartz and large phenocrysts of hornblende	-	Quarry 3	10°52'26.1"N	78°22'26.2"E	
SR - 53	Gneissic zone with porphyroblast indicators showing south side up.	vertical	Quarry 3	10°52'26.1"N	78°22'26.2"E	
SR - 55	Gneissic zone with porphyroblast indicators showing south side up.	vertical	Quarry 3	10°52'26.1"N	78°22'26.2"E	
SR - 56	Fine grained massif charnockite ± garnets?	-	Quarry 5	10°52'24.4"N	78°22'24.7"E	
SR-57	Waxy green coloured, fine grained massif charnockite, little to no visible garnet, dominate mineral is hornblende.	F 38/249	Quarry 5	10°52'29.7"N	78°22'24.2"E	
SR - 58	Fine grained massif charnockite ± garnets?	F 38/250	Quarry	10°52'29.7"N	78°22'24.2"E	
SR-59	Glossy rim surrounding the charnockite, dominated by quartz	-	Quarry	10°52'29.7"N	78°22'24.2"E	
SR - 60	Mafic hornblende rich rim lining the quartz rim	-	Quarry	10°52'29.7"N	78°22'24.2"E	
SR - 61	Dark halo dominated with quartz, hornblende.	-	Quarry	10°52'29.7"N	78°22'24.2"E	
SR - 62	North side of quarry is light grey -green colour charnockite, dominated by hornblende, however no visible opx, appears more felsic variety. Looks like felsic from hill.	-	North side of Quarry 2	10°52'32.8"N	78°22'25.5"E	
SR - 63	Grey granite consisting of pink - red coloured feldspar, plagioclase, biotite?, some magnetite.	-	Western base of Ayyarmalai	10°52'32.3"N	78°22'46.3"E	
SR - 64	Pink granite - k-feldspar, quartz, plagioclase ± dark minerals.	F 80/314	Ayyarmalai	10°52'32.3"N	78°22'46.3"E	
SR - 67	Pegmatite vein within the pink granite	-	Ayyarmalai	10°52'27.4"N	78°22'47.6"E	
SR - 68H	Pink granite - k-feldspar, quartz, plagioclase ± dark minerals.	F 62/236	Ayyarmalai	10°52'27.4"N	78°22'47.6"E	
SR - 70	Lineated pink granite - lineation defined by large hornblende phenocrysts aligned within the pink K-feldspar and quartz matrix.	L 40→267	Southern side of Ayyarmalai base	10°52'25.1"N	78°22'49.7"E	
SR - 71	Pink granite - k-feldspar, quartz, plagioclase ± dark minerals.	-	Sample obtained from further up the hill on southern side			
SR - 80	Grey granite consisting of pink - red coloured feldspar, plagioclase, biotite?, some magnetite. Abundant green waxy dehydration veins running through the outcrops.	-	Northern side of Ayyarmalai base	10°52'32.3"N	78°22'47.1"E	
SR - 82	Lineated pink granite - lineation defined by large hornblende phenocrysts aligned within the pink K-feldspar and quartz matrix.	L 58 →260	Southern side of Ayyarmalai base	10°52'36.3"N	78°22'47.5"E	
SR - 84	Garnet rich charnockite. garnets are quite large in size (<2mm) in respect to other charnockites in the quarry.	-	Quarry 1	10°52'31.1"N	78°22'24.1"E	
SR - 85	Another dehydration similar to sample SR - 86	-	North western side of Ayyarmalai	10°52'32.3"N	78°22'47.1"E	
SR - 86	Abundant veins and splodges of the green waxy rock lithology. Samples taken across the green "incipient charnockite" zone. Quartz is identifiable in the green zone, as well as hornblende. No OPX is visibly identifiable. K-feldspar in the surrounding grey coloured granite appears garnet coloured red and is less abundant than the pink K-feldspar granite behind it. This granite is dominated by quartz 55%, 35% K-feldspar and 10% black minerals. Green vein requires thin section analysis for identification of fine grained minerals.	-	Western Side of Ayyarmalai	10°52'32.3"N	78°22'46.3"E	
SR - 87	Another dehydration similar to sample SR - 86	-	South western side of Ayyarmalai	10°52'36.3"N	78°22'47.5"E
